Ecological momentary assessment

ABSTRACT

Objectives: People with schizophrenia (SCZ) and bipolar illness (BPI) generate self-reports of their functioning that diverge from objective information. It has been suggested that these participants do not base such reports on daily experiences, relying on other information. We used ecological momentary assessment (EMA) to sample socially relevant daily activities in SCZ and BPI and related them to self-reported and observer-rated social functioning and social cognitive ability.

Methods: 71 people with BPI were compared to 102 people with SCZ. Participants were sampled 3 times per day for 30 days with a smartphone-based survey. Each survey asked where they were, with whom they were, what they were doing, and if they were sad. Participants and observers were asked to provide ratings on social functioning and social cognitive abilities at the end of the EMA period.

Results: There was no association between being home or alone and self-reports of everyday social functioning. In contrast, observer ratings were highly correlated with the momentary survey results. Reports of very low levels of sadness were associated with overestimated functioning and participants who were commonly home and alone rated their social functioning as better than participants who were commonly away in the presence of others. Implications: Both SCZ and BPI were marked by a disconnect between momentary experiences and self-reports. The largest effect was overestimation of functioning by participants who reported no sadness. Experience appears important, as participants who were routinely home and alone reported better social functioning than participants who spent more time others.

1. Introduction

Despite multiple advances in the treatment of schizophrenia (SCZ), it remains the leading cause of disability worldwide (Charlson et al., 2018). There is consensus in the field that current functional assessment methods do not adequately capture the daily functioning behaviors of participants with schizophrenia (Ben-Zeev et al., 2012). Part of the limitation is that many functioning measures that rely on self-reports can be influenced by challenges in self-assessment, often referred to as introspective accuracy (Ma & Pinkham, 2015). These challenges extend to self-assessment of cognitive abilities, functional abilities, social cognition, and social outcomes (Durand et al., 2015) and are shared across psychiatric conditions (Strassnig et al., 2018).

These difficulties with introspective accuracy are commonly accompanied by introspective bias, wherein individuals either overestimate or underestimate their functioning (Silverstein and Harvey, 2019). It has been consistently reported in SCZ that overestimation biases are associated with poorer performance on social cognitive and neurocognitive tests (Jones et al., 2019; Gould et al., 2015; Perez et al., 2020); presence of certain types of paranoid ideation (Moritz et al., 2015; Savia et al., 2013), poorer social outcomes (Silverstein et al., 2018), and poorer functional outcomes (Gould et al., 2015; Durand et al., 2015). Both healthy controls (HC) and participants with SCZ who overestimated their social cognitive performance on a momentary basis had poorer performance on social cognitive measures and several neurocognitive tasks as well (Perez et al., 2020), congruent with earlier research on
healthy people suggesting that poor performers often overestimate their abilities (Wager and Icenogle, 1999).

Depressed mood has a complex relationship with self-assessment, in both HC and in people with SCZ. For example, higher scores on self-reported depression scales were correlated with reports of worse social functioning in both HC and people with SCZ (Oliveri et al., 2020). The self-reported absence of sadness in the context of objective adversity has been reported to be associated with overestimation of a range of abilities (Harvey et al., 2017; Harvey et al., 2019; Siu et al., 2015). Strassung et al. (2018) found that in participants with either SCZ or bipolar illness (BPI), the severity of clinically rated depressed mood was associated with self-reported everyday function: the World Health Organization Disability Assessment Scale (WHODAS; Unützer et al., 2010). In that same sample, across diagnoses, participants who were unemployed or living in supported residences or whose parents did not rate themselves as more disabled on the WHODAS than participants who had full-time jobs were living independently. Thus, mood state, as defined at higher clinical ratings of depressed mood on the day of the self-reported disability assessment, was more strongly correlated with self-reported disability than with on-going life experiences with daily living implications (unemployment, supported residential status).

Social cognition is another domain where self-assessment is important (Penny et al., 2008). Participants with SCZ show deficits in performance on tests of social cognition and also in the self-assessment of their social cognitive abilities and their everyday social outcomes (Silberstein et al., 2018). Therefore, they may misinterpret interactions in either overly negative or overly positive directions (Koster et al., 2012; Mueser et al., 2012; Mueser et al., 2015). The ability to correctly interpret social interactions can be lessened in social situations (Carnachio et al., 2017) and high confidence in social cognitive performance predicted poorer social outcomes in people with SCZ (Pinskhan et al., 2018). In order to efficiently assess social cognition, the 8-item Observable Social Cognition Rating Scale (OSCRS; Healey et al., 2015) was developed for use as a self- or informant-report measure. Overestimation of social cognitive abilities, indexed by self-reported OSCRs scores that were greater than those generated by informants, was found to be associated with poorer everyday social outcomes rated by observers (Silberstein et al., 2018).

An alternative strategy for assessment of everyday functioning is that of capturing participant’s daily activities and mood on a momentary basis. The use of ecological momentary assessment (EMA) has held promise in assessing functional outcomes in SCZ and BPI. Recent studies demonstrated the feasibility, sensitivity, reliability, and validity of EMA in assessing social functioning (Granholm et al., 2018). Additionally, confidence when performing social cognitive tests has been reported to be unassociated with actual performance in participants with SCZ and HC (Granholm et al., 2017) and high confidence in social cognitive performance predicted poorer social outcomes in people with SCZ (Pinskhan et al., 2018). In order to efficiently assess social cognition, the 8-item Observable Social Cognition Rating Scale (OSCRS; Healey et al., 2015) was developed for use as a self- or informant-report measure. Overestimation of social cognitive abilities, indexed by self-reported OSCRs scores that were greater than those generated by informants, was found to be associated with poorer everyday social outcomes rated by observers (Silberstein et al., 2018).

2. Methods

2.1. Participants

Participants who met DSM-V criteria for Schizophrenia, any subtype, Schizoaffective Disorder, Bipolar Disorder I or II, with or without current or previous psychotic symptoms participated in this study. They were recruited at three different sites: The University of Miami Miller School of Medicine (UM), the University of California San Diego (UCSD), and The University of Texas at Dallas (UTD). UM participants were recruited from the Jackson Memorial Hospital–University of Miami Medical Center and the Miami VA Medical Center. UTD participants were recruited from the UCSD Outpatient Psychiatric Services clinic, a large public mental health clinic, the San Diego VA Medical Center, and other local community clinics and by word of mouth. UTD participants were recruited primarily from Metrocare Services, a non-profit mental health services organization in Dallas County, TX, and from other local clinics. The study was approved by each University’s respective Institutional Review Board, and all participants provided written informed consent. Diagnostic information was collected by trained interviewers using the Mini International Neuropsychiatric Interview (MINI; Sheehan et al., 1998) and the psychosis module of the Structured Clinical Interview for DSM Disorders–5 (SCID–5; First et al., 2015) and a local consensus procedure was used to generate final diagnoses.

2.1.1. Inclusion/exclusion criteria

To be eligible, participants had to meet criteria for one of the disorders mentioned above. Individuals with bipolar disorder also had to meet a staging model severity of 3 or higher, indicating at least one mood episode recurrence or incomplete remission from a first-episode (Frank et al., 2014). Participants were also required to be on no hospitalizations and to be on a stable medication regimen for a minimum of...
six weeks with no medication dose changes >20% for a minimum of two weeks. All antipsychotics or antipsychotic combinations were accepted. For participants in both diagnostic groups exclusion criteria included: (1) history of current medical or neurological disorders that may affect brain functioning, e.g., CNS tumors, seizures, or loss of consciousness for over 15 min), (2) history of current intellectual disability (IQ < 70) or pervasive developmental disorder according to the ADOS-2 criteria, (3) presence of substance use disorder other than tobacco in remission for at least six months, (4) visual or hearing impairments that interfere with assessment, and (5) lack of proficiency in English. Cases with a Wide Range Achievement Test-3rd edition (WRAT-3; Jastak, 1983) grade Equivalent score of less than 8th grade was also not enrolled because of concerns that they would not be able to read the consent form and might have other challenges in reading the instructions for the EMA queries and self-assessment scales. We also excluded all potential participants who did not complete the clinical assessment at endpoint, regardless of the amount of EMA data collected prior to that assessment.

2.2. Overview of the study methods
Participants had a brief office visit at the beginning of the study. They received diagnostic and clinical assessments and then began the 30-day EMA period described below. At the end of the EMA period, a follow-up visit took place, with a repeat of the baseline clinical assessments and a detailed performance-based assessment of neurocognition, social cognition, and functional capacity. Participants also self-reported on their everyday functioning and their social and neurocognitive abilities. Observers who had not performed the baseline assessments performed these follow-up assessments. The assessment time frame for all self-report and observer ratings of functioning were “the last month,” which is convergent with the 30-day EMA period. These analyses report on a subset of this very detailed assessment.

2.3. Assessments

2.3.1. Social cognitive ability
Social cognitive ability was assessed with the Observable Social Cognition Rating Scale (OSCARs). Both observers and participants completed the OSCARS (Healey et al., 2015), an 8-item interview-based assessment of social cognition. Each question on the OSCARS is made up of a question probing a domain of social cognition (attributions, style, cognitive rigidity, theory of mind, emotional perception, and jumping to conclusions). For each item, study participants ranked their abilities using a 7-point scale, with higher rankings translating to greater impairment. For this study we used the total score, which was the sum of all 8 items for both observers and participants. The internal consistency of the OSCARS was found to be 0.80 in participants in the development study. In a recent study, the OSCARS demonstrated adequate psychometric properties to detect functioning deficits in participants with schizophrenia and efficiently identify individuals in need of additional assessment or psychosocial interventions (Halverson et al., 2020).

2.3.2. Real-world functioning
Real-World Functioning was rated with the 31-item version of the Specific Levels of Functioning (SLOF; Schneider and Strauss, 1983). The SLOF is an informant- or self-rated assessment of functioning. In this study we focused on the interpersonal functioning scale because of our EMA data on social activities. A trained rater administered the measure to participants to obtain a self-report of functioning. In line with past use of this scale in several studies, observers completed the scale as if it were a questionnaire (Harvey et al., 2011; Pilkham et al., 2018). Each item was rated from 1 to 5, with higher scores reflecting better functioning.

2.4. Procedures

2.4.1. All-source observer SLOF and OSCARS ratings
In this study, we generated ratings on the basis of all sources of information. In our previous studies that recruited at these sites (Harvey et al., 2011; Pilkham et al., 2016, 2018), we discovered that we were only able to obtain a high-quality informant (high contact clinician; caregiver who lived with the participant) for about 75% of potential participants. Rather than reject cases without such an informant, we used an all source observer rating procedure as we described before (Harvey et al., 2019). Raters who interviewed the participants on the SLOF and the OSCARS also had access to informant reports if available for these two rating scales as well as clinical and performance-based assessment data (including social cognitive test performance). Raters were instructed to make their ratings on the basis of what they thought was the correct rating, regardless of the source of information, and to consider information from their own observations of the participant when generating their ratings. These raters were unaware of any EMA data on the participants.

2.4.2. EMA procedures
A Samsung smartphone with Android OS was used to deliver EMA surveys. The device was provided by the investigators to participants. Participants received text messages with weblinks to EMA surveys 3 times daily for 30 days, with data instantly uploaded to a cloud-based data capture system. The signals occurred at stratified random intervals that varied from day to day within, on average, 2-hour windows starting at approximately 9:00 AM and ending at 9:00 PM each day. The first and last daily assessment times were adjusted to accommodate each participant’s typical sleep and wake schedules. All responses were time-stamped and were only allowed within a 1-hour period following the signal, although participants had the option of silencing alarms for 30-minute intervals (e.g., during naps, classes). We selected this one-hour window in contrast to other intervals (e.g., 15 min) because of our findings in previous studies that participants commonly engaged in only one activity in the past hour (Strassberg et al., 2020), and were also either home or away for the entire past hour in 85% of the surveys returned (Granholm et al., 2020; Parrish et al., 2020). Thus, the longer window was aimed at augmentation of adherence.

An in-person training session (typically <20 min) was provided on how to operate and charge the device and respond to surveys, including the meaning of all questions and response choices. EMA surveys were check-box questions asking about behaviors performed since the previous survey. The first question asked about the participant’s location, with the following options: at my home, at home of family, at home of friends, at work, at outpatient medical visit, in hospital, at community center, in public business/store, in vehicle, outside walking, in class/educational setting, inside other, and outside other. Then participants were asked about who they were with. Options for this question included alone, spouse or partner, friends, other family members, pets, healthcare providers, other known people, and unknown people. The subsequent screens then used branching logic to delivered customized surveys that asked what the participant was doing based on where they were and with whom they were at the present time. Being with a pet, but not a human, was considered “alone”.

Mood questions included sadness, happiness, anxiety, and relaxation. All mood items were scaled with a 1-7 range, with higher values indicating greater severity. We examined only sadness, for two reasons. First is because other mood states have not been reported to be associated with systematic biases in IA. The second is because of potential redundancy. In the entire sample, the MMPI association (adjusting for random intercept, day, and survey) between the up to 50 happy ratings and time-linked linked sad ratings was: $X^2(1) = 3771.1$, $p = 3.2 \times 10^{-6}$, $B = -0.48$ and in previous studies of smaller samples, less sadness and more happiness were essentially redundant with each other (Depp et al., 2016).
2.5 Data analyses

Data analyses were performed using the SPSS edition 26 Generalized Linear Models (GLM) module (IBM Corporation, 2020). In order to perform a sophisticated examination of all of the survey data, we used a mixed model repeated measures analysis of variance (MVRM) where we predicted self and observer reports of everyday interpersonal functioning and social cognitive abilities with information about where the participant was, who they were with, and their current mood. We then sequentially added diagnosis (schizophrenia spectrum vs. bipolar disorder) and momentary assessments of sadness to the models.

In the final analyses, we examined the difference between self- and observer reports on social functioning and social cognitive abilities, expressed as the extent of overestimation of self-reports compared to observer ratings. We used the same analysis strategy for these models as well.

3. Results

Descriptive information on the participants with bipolar disorder (n = 71) and schizophrenia (n = 102) is presented in Table 1. Participants with bipolar disorder had more education and higher WRAT-3 reading scores than the participants with schizophrenia. In terms of functional milestones, participants with bipolar disorder were more likely to have ever been married or equivalent, with no significant differences in current residential or employment status. There was a total of 11,907 EMA surveys with non-missing data for being home, being alone, and the sadness item for cases with both SOLO and OSCARS self-report and observer ratings with 7110 from SCZ and 4797 from BPI. Adherence to surveys was 78% for participants with SCZ and 75% for participants with BPI.

Table 2 presents the mean and standard deviations for the observer reported and self-reported social functioning and social cognition variables. As can be seen in the table, there were no significant diagnostic group differences in self-reported social functioning, while the observer ratings suggested that the participants with BPI had better social functioning. Participants with SCZ reported they had significantly worse social cognitive ability than the participants with BPI; observer ratings were consistent with this difference.

Paired t-tests indicated that participants with schizophrenia rated their social functioning significantly better than the observers, t(110) = 3.45, p = .012, while there was no difference on average between their self-reports on the OSCARS and the observer ratings, t(110) = 0.08, p = .91. Participants with BPI generated reports of their social functioning that did not differ from reports of the observers, t(70) = 0.41, p = .68. However, they reported that their social cognitive functioning was significantly better than the observer ratings, t (70) = 3.05, p = .005.

3.1 MVRM analyses of self-reported and observer rated social functioning and social cognition

The analyses of self-reported and observer rated social functioning and social cognitive ability are presented in Table 3. When predicting self-reported social functioning with home, alone, and their interaction, the model did not improve on the null model. When diagnosis was added to the model, the model also was not improved. When momentary sadness was added into the model, the model achieved significance compared to the null model. There were statistically significant effects of momentary sadness, diagnosis, and answering more surveys while away from home, but no effects of being alone or interactions of being home and alone on self-reported social functioning. Participants who answered more surveys while at home reported better social functioning. EM Mean = 24.48, SE = 0.13, than those who answered surveys from away. EM Mean 24.01, SE = 0.09.

When observer-reported social functioning was examined with the same strategy, observer rated social functioning was statistically higher in participants who answered more surveys while away from home. When diagnosis was added to the model, there were statistically significantly higher observer rated scores for participants with BPI and participants who answered more surveys while home alone got the lowest ratings from observers. When momentary sadness was added there were statistically lower observer-rated functioning scores associated with greater momentary sadness.

Note: For SOLO: higher scores are better. For OSCARS, higher scores reflect more impairment. All difference scores represent over-estimation with positive values.
When we modeled self-reported social cognitive ability, all of the models improved on the null model. Participants who answered more surveys while alone and participants who answered more surveys away from home rated themselves as having better social cognitive ability. Bipolar patients rated themselves as having better ability and higher momentary sadness predicted self-reports of poorer social cognitive abilities.

Observed social cognitive ability was examined with the same modeling strategy and all of the models improved on the null model. Participants who answered more surveys away from home were rated as having better social cognitive abilities, as were participants who answered more surveys while another person. The participants who answered more surveys while home alone got the lowest observer ratings. Bipolar patients were rated higher, as were participants who answered more surveys while another person.

3.2. MMRR of over estimation

In the final two MMRR analyses, we modeled the overestimation of social functioning and social cognitive ability. Table 4 presents the results of these analyses, as well as the EM Means from the final step in the model. For social functioning, the model became significant when diagnosis was added. Participants with schizophrenia significantly overestimated their functioning compared to participants with bipolar disorder. Participants who answered more surveys while home overestimated their functioning the most and participants who answered more surveys away from home underestimated their functioning. Participants who endorsed the complete absence of sadness overestimated their functioning compared to observer ratings, while increasing severity of momentary sadness was associated with a U-shaped curve, with congruence between self-reports and observer ratings at moderate levels of sadness and under-estimation at the highest levels.

For overestimation of social cognitive ability, the model became significant when diagnosis was added. Participants with BPI significantly overestimated their functioning compared to participants with schizophrenia. However, across both groups overestimation of social cognitive abilities was associated with answering more surveys while being home and alone. Finally, reduced levels of momentary sadness were associated with overestimation of social cognitive ability, which manifested the same U-shaped curve across moderate and high levels of momentary sadness.

4. Discussion

Participants with schizophrenia and bipolar disorder generated self-ratings of their everyday social functioning that were uncorrelated with 30 days of real-world sampling of socially relevant information, indicating that they were home and if they were alone. In contrast to the disjunction between 30 days of EMA sampling and self-reports of functioning, observer ratings on the same scales were associated with the results of EMA survey sampling. These findings suggest that being more often home and alone was associated with a clinical impression of poorer social functioning and poorer social cognition. Thus, our hypothesis that participants with SCZ and BPI would be challenged in terms of the ability to utilize their daily activities to generate self-reports of functioning congruent with observer ratings was confirmed. The rates of being home and alone in this sample of participants with SCZ and BPI was very similar to our previous studies of participants with SCZ compared to HC (Granh olm et al., 2020; Parrish et al., 2020), suggesting that the EMA data are representative of this population. We also confirmed our hypothesis that momentary sadness ratings would systematically associate with self-reports of both social functioning and social cognitive ability. There were opposite introspective biases associated
with higher and lower momentary sadness ratings. Our exploratory hypothesis that there would not be major differences in IA and IT between the groups was confirmed. Participants with BPI were rated as higher functioning and more capable in social cognitive abilities, but diagnosis did not contribute toward the use of daily experience to generate self-assessments of social cognition.

Overestimation of social cognitive abilities and social functioning was greatest in participants who answered more surveys while alone, and for self-reported social cognition, home alone. Participants who answered more surveys while away with someone underestimated their social functioning and social cognition compared to observer ratings. We had previously found participants with SCZ who had never been employed reported that their work skills were equivalent to and their ability to perform everyday activities was superior to SCZ participants who were currently employed full time (Gould et al., 2013), despite performing notably more poorly on measures of neurocognition (effect size = 1.0 SD). The current results suggest that variation in ongoing social experiences may predict self-assessments of abilities as well and that this may lead to judgments of functioning that are accurate to underestimated.

These data regarding momentary sadness are congruent with previous findings that suggested that extremely, and probably unrealistically, low scores on self-report and clinician depression rating scales are associated with overly positive self-assessments of real-world functioning (Harvey et al., 2017, 2019). Responding to EMA surveys with momentary reports of moderately sad moods was associated with generation of self-assessments were congruent with observer ratings. Finally, the lack of experience hypothesis seems supported by findings that participants who responded to fewer surveys in the company of other people rated both their social functioning and their social cognitive abilities as better than participants who are responding to surveys while away from home in the company of others.

As in any study, there are limitations in this dataset. The sample sizes are not equal in terms of diagnosis, but the current study is still one of the largest dense-sampling studies of EMA in severe mental illness to date. Demographic differences, sex distributions, history of marriage, and educational attainment were detected between participants. These same differences are common even in very large population-based studies (Harvey et al., 2014). Participants were not fully adherent with sampling and missing data could be being un able to respond to survey invitations while performing certain activities, some of which could have been performed away from home in the company of others. Overcoming this concern is the fact that the participants with the top 20% adherence in this study (3 or fewer missed surveys) answered 35% of the surveys while away and those whose adherence was lowest (40 or more missed surveys) answered 40% of their surveys while away from home. There was no HC sample, although the EMA results for the participants with SCZ in this study were very similar to those seen in participants in previous comparative studies with HC. As noted above, previous studies also have found similar patterns of overestimation of abilities and similar correlates of these overestimations in HC and SCZ. Self-reported depres sion was also associated with reports of both poorer social functioning and poorer social cognition in HC and in participants with SCZ, in an independent sample using the same rating strategies and scales (Oliver et al., 2020). We did not measure the full range of depressive symptoms in this study on a momentary basis. We have shown in other EMA studies that momentary reports of sadness collected with EMA are cross sectionally and longitudinally correlated with in-person clinical assessments (Targum et al., in press).

Another important interpretive issue is the quality of social interactions, and not just the quantity. In an analysis of the quality of behaviors, including social ones, in this database (Strassng et al., submitted), there were some relevant findings. Explicitly social activities, including “social activities” or “visiting family” constituted 2.1% of all survey responses. The second finding was that unproductive activities (sleeping, smoking, just sitting, nothing), accounted for 32% of all surveys, but were significantly less likely when the participant was not alone. Productive activities, home or away, were more common when not alone, thus suggesting a generalized positive association with social contact and productivity. In a previous EMA study it was shown that suicidal ideation was not associated with the number of social contacts or perceptions of competence during the interactions, but rather the belief that social interactions were just not worth the effort (Deppe et al., 2016). Thus, the association between social contact, motivation to engage in social behavior, and other productive outcomes clearly requires further attention.

4.1. Conclusions

This study provides additional information suggesting that participants with severe mental illness do not rely on their actual longitudinal activities when generating global self-reports of functioning. However, observer ratings of social functioning were significantly correlated with daily socially-relevant activities measured longitudinally with EMA. Participants reporting very low levels of momentary sadness tended to generate ratings of their functioning that were positively biased compared to those generated by observers. Similarly, participants with lower levels of momentary social engagement (i.e., home and alone) generated ratings that were also positive biased, particularly compared to participants who were away from home with someone else. These data suggest that self-reports of everyday functioning coming directly from participants with SMB may be less useful than data collected on a momentary basis as a phenotype for the correlates of neurobiological or genomic variables or the effects of treatment.

CRediT authorship contribution statement

Drs. Harvey, Pinkham, Moore, and Deppe designed the study. Dr. Harvey ran the data analyses in consultation with Drs. Strassng and Durand. Drs. Durand and Strassng wrote the first draft of the manuscript. All authors have reviewed and edited the paper and approve the final version.
